Advance Python Assignment

Topic-2: Reading Data from Keyboard

Q1. Explain the use of input() function in Python.

Ans.
The input() function in Python is used to take data from the user during program execution. It helps in making programs interactive by allowing users to enter values from the keyboard. The data entered is stored as a string by default, so it may need conversion into other types when required. This function is widely used in simple and advanced programs to accept user input and process it accordingly.

Example:

```
user = input("Enter your name: ")
print("Welcome", user)
```

Q2. Explain type conversion of user input in Python.

Ans.
Type conversion is used to change the data type of input values into the required format. Since input() takes all values as strings, we use functions like int(), float(), and str() to convert them. This is important when performing calculations or comparisons. Proper type conversion ensures that the program works correctly with user data.

Example:

```
a = int(input("Enter number: "))
b = int(input("Enter number: "))
print("Sum:", a + b)
```
